

EFFECTS OF DIFFERENT REINTERVIEW TECHNIQUES ON ESTIMATES OF SIMPLE RESPONSE VARIANCE

Introduction

This report is one of a series of evaluation and research reports providing measures of the quality of the 1960 Censuses of Population and Housing. The subject of this report is a replication study following the census enumeration, designed to yield estimates of the simple response variance of census statistics.

Project A of the 1960 evaluation program included three studies designed to measure the variances in census statistics that could be attributed to crew leaders, enumerators, coders, and respondents. Response Variance Study I was designed to give estimates of enumerator and crew leader effects. The results of this study appeared in ER60, No. 7 of this series. Response Variance Study III was designed to yield estimates of the effects of the coders on census data. The results from this study are available in ER60, No. 9 of this series. Response Variance Study II was a replication study and was designed to give estimates of the trial-to-trial variability of census statistics, the simple response variance. The results of that study are the subject of this report.

The sample of housing units and persons included in the replication study was a subsample of those originally included in Response Variance Study I. Let us briefly review the sample selection process. A probability selection was made of 50 census district offices from the 290 census district offices in which a two-stage census procedure was to be used. In each of the 50 district offices, a selection of two neighboring crew leader districts was made. Within these crew leader districts, all special enumeration districts (ED's) such as jails, hospitals, dormitories, etc., were eliminated from selection. Then, a selection of about two-thirds of the ED's in the crew leader districts was made. All group quarters such as rooming houses were eliminated from the study.

From the ED's included in Response Variance Study I, a selection of five in each district office was made with probability proportionate to size. Twenty units from each of the five ED's were selected and designated as Sample I units; from one ED, an additional 20 units were selected and designated as Sample II units.

Thus, for the replication study, there were two samples--one of about 5,000 housing units and one of about 1,000 units.

Description of the Replication Study

To estimate the simple response variance, it is necessary to get two independent measurements of the characteristic, using the identical measurement method on both trials. It is also necessary that the response to the second interview not be affected by the first interview. A flaw occurring in every attempt to measure the simple response variance by means of a reinterview is the lack of independence between the original interview and the reinterview. A person visited twice and asked the same questions may tend to remember his original responses and repeat them. If the time period between the two visits is short, this may be a serious problem. The lack of independence may be even worse when the person is

reminded of his original response and asked to explain the discrepancy if his second response is different from the first. In the replication study, persons at selected housing units were asked to respond twice, but, in order to decrease the dependence of the second response on the first, an enumerator was not assigned a unit in the reinterview that had been in his original census assignment. The enumerators had no knowledge of the original census responses.

Another serious problem in estimating the simple response variance is that the data-collection method in the reinterview must be identical with that of the original interview. This is seldom the case. The data-collection method specifies the questionnaire to be used, the kinds of people who are to be interviewers, the training of the interviewers, whether people are asked to respond by mail or by direct interview, etc. Thus, in two studies from which estimates of the simple response variance were made, the reinterviews were conducted 4 to 7 months after the census, using a very detailed, probing questionnaire, with an intensive training of superior interviewers. (See ER60, Nos. 3, 4, and 10.) In one of these studies, the reinterviewers were given the original census responses and they asked the respondents to explain any differences between the census and reinterview responses. These studies provide biased estimates of the simple response variance.

In still another study from which estimates of the simple response variance were made, the second interview was the Current Population Survey. In this monthly survey conducted by the Bureau of the Census, a specially trained staff of permanent interviewers are trained on the use of a questionnaire quite different from the census questionnaire. This is also not the same data-gathering technique used in the census.

The replication study was designed to study some of the effects of using a different data-gathering technique and also to provide less biased estimates of the simple response variance. As mentioned in the Introduction, there were two samples included in the replication study. Different data-gathering techniques were used in the two samples as follows:

In Sample I, composed of 5,000 housing units, enumerators were sent to the housing units and the persons at the units responded by means of a direct interview.

In Sample II, composed of 1,000 housing units, questionnaires identical with the census questionnaires were mailed to the housing units. The householder was asked to mail in the completed questionnaires within 3 days. Nonresponses and inconsistencies were followed up by enumerators. The procedure was identical to the census procedure.

In both samples, the householders were asked to make the second response within 2 or 3 weeks of the census. In both samples, the reinterview questionnaire was identical to the census questionnaire except for the color of the paper used. In both samples, the enumerators were a

group of census enumerators who were willing to accept additional assignments. There was no effort to select only the best enumerators. Also, the enumerators were paid the same way as they were in the census. In both samples, one responsible member of the household could answer for all household members; no attempt was made to select the "best" respondent in the household.

Thus, we see that in Sample II, the exact census procedure was used--self-enumeration with followup. In Sample I, a somewhat different procedure was used, but still closer to the census procedure than other studies from which estimates of the simple response variance have been made. However, there are still difficulties. Since the second interview was so close in time to the first, the respondent may have tended to make the same response. Especially in Sample II, when the householder received a second census schedule, the same person who filled in the original schedule may have been the respondent and tended to fill in the questionnaire as he did originally.

In this report, the data from Samples I and II are compared with each other and with data from other reinterview studies. Some interesting differences are observed, and a detailed analysis is given in later sections of this report.

Processing of the Data

The data from the reinterview questionnaires were transcribed by census enumerators to the same kinds of schedules used in the census. Again, this was identical to the census procedure. Then, when the bulk of enumeration books had passed through the coding sections, the enumeration books with the reinterview data were assigned to the coding sections. Quality-control procedures identical with those of the census coding procedure were used. Thus, the coding of the schedules from the replication study was identical to the coding procedure of the census schedules.

The census schedules were microfilmed and converted to magnetic tape and passed through an extensive editing process. In the editing process, inconsistencies of data were eliminated and imputations for nonresponses were made. It was not feasible to pass the schedules from the replication study through this edit. Therefore, to make the data from the two sources comparable, the census schedules were remicrofilmed. Thus, the data in this report pertain to census and replication study schedules before editing for nonresponse and inconsistencies.

About 96 percent of the Sample I schedules and 97 percent of the Sample II schedules were successfully matched with census schedules and remained in the study. Thus, we have data on about 4,800 housing units and 14,000 persons in Sample I and 970 housing units and 2,800 persons in Sample II. The data from each housing unit and person were weighted to reflect the probabilities of selection. Thus, the data in tables I through 88 are weighted estimates of totals for the areas of the United States in which a two-stage census was conducted.

The Mathematical Model

The mathematical model used in the Response Variance Study is the model described by Hansen, Hurwitz, and Bershad [2]. This model is illustrated as follows:

Unit number	Trial number				Expected value over trials
	1	2	- - -	t - - -	
1	x_{11}	x_{12}		...	
2					
.					
j				x_{jt}	$E(x_{jt} j)$
.					
N					
					$E(x_{jt})$

The variable x_{jt} refers to the t-th trial on the j-th unit. The conditional expected value for the j-th unit over all trials is $E(x_{jt}|j)$; the expected value over all trials and units is $E(x_{jt})$.

Thus, the variance of a single observation, x_{jt} , can be written as:

$$\begin{aligned} \text{Var}(x_{jt}) &= E[x_{jt} - E(x_{jt})]^2 \\ &= E[x_{jt} - E(x_{jt}|j) + E(x_{jt}|j) - E(x_{jt})]^2 \\ &= E[x_{jt} - E(x_{jt}|j)]^2 + E[E(x_{jt}|j) - E(x_{jt})]^2 \\ &\quad + 2E[x_{jt} - E(x_{jt}|j)][E(x_{jt}|j) - E(x_{jt})] \quad (1) \end{aligned}$$

If expectations are taken first with respect to trials and then with respect to samples, the expectation of the last term is zero. Then,

$$\begin{aligned} \text{Var}(x_{jt}) &= E[x_{jt} - E(x_{jt}|j)]^2 \\ &\quad + E[E(x_{jt}|j) - E(x_{jt})]^2 \quad (2) \end{aligned}$$

The first of these terms is referred to as the simple response variance and is denoted as σ_s^2 ; the second is the sampling variance and is denoted by σ_R^2 . Thus, we see that the total variance of a single observation is the sum of the sampling variance and the simple response variance or

$$\text{Var}(x_{jt}) = \sigma_s^2 + \sigma_R^2$$

Suppose we are interested in the mean of the n observations resulting from a single trial on a simple random sample of n units.

Let,

$$\bar{x} = \sum_j \frac{x_{jt}}{n}$$

Then,

$$\begin{aligned} \text{Var}(\bar{x}) &= \frac{1}{n^2} E \left[\sum_j^n \left(x_{jt} - E(x_{jt}|j) \right)^2 \right] \\ &\quad + \frac{1}{n^2} E \left[\sum_j^n \left(E(x_{jt}|j) - E(x_{jt}) \right)^2 \right] \\ &\quad + \frac{2}{n^2} E \left[\sum_j^n \left(x_{jt} - E(x_{jt}|j) \right) \right] \\ &\quad \times \left[\sum_j^n \left(E(x_{jt}|j) - E(x_{jt}) \right) \right] \end{aligned} \quad (3)$$

By expanding these terms and looking at the expected values of each of these terms, we find that

$$\begin{aligned} \text{Var}(\bar{x}) &= \frac{\sigma_R^2}{n} \left[1 + (n-1)\rho_R \right] + \frac{\sigma_s^2}{n} \left[1 + (n-1)\delta_s \right] \\ &\quad + \frac{2(n-1)}{n} \sigma_{rs} \end{aligned} \quad (4)$$

where

$$\rho_R = \frac{E \left[x_{jt} - E(x_{jt}|j) \right] \left[x_{kt} - E(x_{kt}|k) \right]}{E \left[x_{jt} - E(x_{jt}|j) \right]^2} \quad j \neq k$$

and is the correlation of response deviations of different units in the same trial. The term, δ_s , is

$$\delta_s = \frac{E \left[E(x_{jt}|j) - E(x_{jt}) \right] \left[E(x_{kt}|k) - E(x_{kt}) \right]}{E \left[E(x_{jt}|j) - E(x_{jt}) \right]^2} \quad j \neq k$$

and is the correlation of sampling deviations of different units in the same sample. Also σ_{rs} is defined as

$$\sigma_{rs} = E \sum_{j \neq k} \left[(x_{jt} - E(x_{jt}|j)) (E(x_{kt}|k) - E(x_{kt})) \right]$$

In ER60, No. 7 of this series, we presented estimates of the quantity $\rho_R \sigma_R^2$ for many different items. In this report, we estimate σ_R^2 from a subsample of the same households. By dividing $\rho_R \sigma_R^2$ by σ_R^2 , we get estimates of ρ_R , the intraclass correlation of response deviations of different units in the same interviewer's assignment. However, since we may underestimate σ_R^2 as will be shown, we may overestimate ρ_R .

Let us now turn to the method we use to estimate σ_R^2 . We are concerned with a sample of persons who were asked to respond twice to the census questionnaire. We define a statistic g , which is called the gross difference rate.

$$g = \frac{1}{n} \sum_j^n (x_{Gj1} - x_{G'j2})^2 \quad (5)$$

In this equation, x_{Gj1} is the response of the j -th unit on the first trial under general conditions G and $x_{G'j2}$ is the response of the same unit on the second trial under general conditions G' . In order to measure the simple response variance, we try to make G and G' identical. These general conditions include such things as the organization sponsoring the survey, the questionnaire used, the kinds of people used as interviewers, the way the data are processed, etc.

We shall expand g and look at its expected value.

$$\begin{aligned} g &= \frac{1}{n} \sum_j^n \left[(x_{Gj1} - E(x_{Gj1}|G,j)) - (x_{G'j2} - E(x_{G'j2}|G',j)) \right] \\ &\quad + \left(E(x_{Gj1}|G,j) - E(x_{G'j2}|G',j) \right)^2 \end{aligned}$$

where $E(x_{Gj1}|G,j)$ is the conditional expected value of x_{Gj1} for the j -th unit under general conditions G and $E(x_{G'j2}|G',j)$ is defined similarly.

$$\begin{aligned} g &= \frac{1}{n} \sum_j^n \left[x_{Gj1} - E(x_{Gj1}|G,j) \right]^2 + \frac{1}{n} \sum_j^n \left[x_{G'j2} - E(x_{G'j2}|G',j) \right]^2 \\ &\quad + \frac{1}{n} \sum_j^n \left[E(x_{Gj1}|G,j) - E(x_{G'j2}|G',j) \right]^2 \\ &\quad - \frac{2}{n} \sum_j^n \left[x_{Gj1} - E(x_{Gj1}|G,j) \right] \left[x_{G'j2} - E(x_{G'j2}|G',j) \right] \\ &\quad + \frac{2}{n} \sum_j^n \left[x_{Gj1} - E(x_{Gj1}|G,j) \right] \\ &\quad \times \left[E(x_{Gj1}|G,j) - E(x_{G'j2}|G',j) \right] \\ &\quad - \frac{2}{n} \sum_j^n \left[x_{G'j2} - E(x_{G'j2}|G',j) \right] \\ &\quad \times \left[E(x_{Gj1}|G,j) - E(x_{G'j2}|G',j) \right] \end{aligned}$$

We now look at the expected value of g over all trials and samples. The last two terms have an expected value of zero. Thus, we find that

$$E(g) = \sigma_R^2 G + \sigma_R^2 G' + B^2 - 2\gamma_R \sigma_R \sigma_{RG} \quad (6)$$

where the terms are defined as follows:

$\sigma_R^2 = E \left[x_{Gj1} - E(x_{Gj1}|G,j) \right]^2$ is the simple response variance under general conditions G .

$\sigma_{R,G'}^2 = E[x_{G',j2} - E(x_{G',j2}|G',j)]^2$ is the simple response variance under general conditions G' .

$B^2 = E[E(x_{G,j1}|G,j) - E(x_{G',j2}|G',j)]^2$ is the square of the difference in the expected values of the responses for identical units under the two sets of conditions, G and G' .

$$\gamma_{R,G,G'} \sigma_{R,G} \sigma_{R,G'} = E[x_{G,j1} - E(x_{G,j1}|G,j)]$$

$\times [x_{G',j2} - E(x_{G',j2}|G',j)]$ is the covariance between the response deviations of the first trial and the second trial. If the two trials are entirely independent, this term will be zero.

If the same conditions apply at both the census and reinterview, i.e., $G = G'$, then

$$B^2 = 0 \text{ and } \sigma_{R,G}^2 = \sigma_{R,G'}^2$$

Then,

$$\begin{aligned} E(g) &= 2\sigma_{R,G}^2 - 2\gamma_{R,G} \sigma_{R,G}^2 \\ &= 2\sigma_{R,G}^2(1 - \gamma_{R,G}) \end{aligned}$$

Then, by dividing g by 2, we have an underestimate of the simple response variance by the factor $(1 - \gamma_{R,G})$, where $\gamma_{R,G}$ is the correlation between the response deviations at the two trials. This situation may be taken to be that of Sample II since the conditions of the replication were, so far as possible, made identical to the census conditions.

Sample I presents a somewhat more complicated picture, since $G \neq G'$. Thus, the expected value of g is shown in equation (6). Then, comparing the results of Samples I and II, we may find that the gross difference rate from Sample I is larger than that from Sample II. This may be due to the expected values of the two procedures being different so that B^2 is large, or it may be due to the simple response variance of the enumerative procedure being larger than that of the mail with followup procedure, or it may be due to the term $\gamma_{R,G}$ having different values in Samples I and II. We should like to know which of these factors is responsible for larger gross difference rates when they occur.

To see whether it is the difference in the expected values given by different procedures or whether it is a difference in the simple response variances or the value of $\gamma_{R,G}$, we shall look at an estimate of B , namely

$$B' = \frac{1}{n} \sum_j (x_{G,j1} - x_{G',j2}) \quad (7)$$

We shall do this for both Samples I and II. In Sample II, though the procedures were the same in the census and reinterview, perhaps having a second exposure to the

questions caused a difference. If there is no great difference between the estimates B' for the two samples, we shall assume that differences in the gross difference rates are caused by differences in simple response variances or differences in the values of $\gamma_{R,G}$.

A schematic representation of the results of the census and reinterview follows for the number of persons reported as being in a given class.

Reinterview results	Census results		Total
	In class	Out of class	
In class.....	a	b	a+b
Out of class.....	c	d	c+d
Total.....	a+c	b+d	n = a+b+c+d

The number of persons who said they had a given characteristic in the census is $a+c$. The corresponding number from the reinterview is $a+b$. The number who agree in both surveys that they have the characteristic is a , and so forth. Then, the gross difference rate can be written as

$$g = \frac{b+c}{n} \quad (8)$$

Similarly

$$B' = \frac{c-b}{n}$$

We shall use $g_1/2$ as an estimate of the simple response variance for the items from Sample I, and $g_2/2$ as an estimate of the simple response variance for the items from Sample II. In both cases, this implies that the correlation between response deviations in the census and reinterview is taken to be negligible.

In what follows we shall ignore the effects of any correlated component of response variance which is due to interviewers, coders, crew leaders, etc., and assume that the total variance of a statistic is the sum of the sampling variance and the simple response variance. (See Hansen, Hurwitz, and Pritzker [3].) The index of inconsistency, I , is defined to be the simple response variance divided by the total variance which is equal to PQ where P is the proportion of the population in a given category and $Q = 1-P$. We estimate I by the following:

$$\hat{I} = \frac{g/2}{s^2} \quad (9)$$

where s^2 is an estimate of PQ . There are several different estimators of PQ . We have taken as an estimate of PQ the average computed from the two sets of responses. Thus, we estimate I by

$$\hat{I} = \frac{g/2}{\frac{p_1 q_1 + p_2 q_2}{2}}$$

where p_1 is the proportion of persons reported in the category in the original interview, and p_2 is the proportion in the reinterview and

$$q_i = 1 - p_i, \quad i = 1, 2.$$

The index of inconsistency ranges between zero and one. As the index gets larger, a greater proportion of the total variance of an item is due to variability in response. Large values of I are an indication that more resources should be expended in designing a better question, in training interviewers better, or in some other way trying to reduce the variability in response. However, the estimate of I is also a function of the size of the class interval and the number of class intervals. For example, in the income items, most of the intervals are of width \$500, with some \$1,000 and the last one containing everything \$10,000 and over. The index for the last category may be smaller due to the larger interval.

We shall use the general rule of thumb in the interpretation of the index of inconsistency that indexes of less than .20 are small, those between .20 and .50 are moderate and those over .50 are large. For characteristics such as age and marital status the indexes are small, usually less than .10, indicating that response variability is not a major problem for these items. For educational attainment, the indexes lie between .20 and .40 indicating that there is some difficulty in reporting consistently. For many income items and labor force items, the indexes are over .50, indicating that there is a need to improve the question or the data-collection method to eliminate the variability in response.

In the results, we show estimates of I for all items except those based on samples of less than 100, or where the proportion of the population in a given category is less than .01. Tepping [5] has shown that in these cases the estimates of I are badly biased and are subject to large sampling variances. For other cases when the sample size is small and the index is large, we get estimates of the index which are biased upward. In these cases, the estimated standard errors are underestimates and we do not show them. Such cases are footnoted in the tables. For all other items, we show the estimates of I with their standard errors. We also show an L-fold index of inconsistency which is a weighted average of the individual indexes, the weights being the values of pq for the categories considered. A discussion of this L-fold index is given by Bershad in [1].

The sampling error of the estimate of the index of inconsistency has been approximated by using a linearization technique. After expanding the index of inconsistency in a Taylor series, we use the variance of the linear term in the expansion as an estimate of the variance of the estimate of the index of inconsistency. Tepping [5] has shown that for cases that involve a reasonably large sample and in which p is not too close to zero or one, this estimate of sampling error has a very small bias and a small sampling error.

To simplify somewhat the expression for the estimate of the variance of the index of inconsistency, we shall rewrite the expression for the index in terms of proportions. Thus,

$$p_1 = \frac{a}{n}, \quad p_2 = \frac{b}{n}, \quad p_3 = \frac{c}{n}, \quad p_4 = \frac{d}{n}$$

Then,

$$\hat{I} = \frac{p_2 + p_3}{(p_1 + p_2)(p_3 + p_4) + (p_1 + p_3)(p_2 + p_4)} \quad (10)$$

The linear approximation to \hat{I} is

$$I + \sum_{i=1}^4 p_i \frac{\partial \hat{I}}{\partial p_i}$$

where I and the partial derivatives $\frac{\partial \hat{I}}{\partial p_i}$ are evaluated at the expected values $E p_i = p_i$. The variance is then approximated by

$$d' Ad \quad (11)$$

where d is the vector of derivatives $(\partial \hat{I} / \partial p_i)$, d' is its transpose, and A is the variance-covariance matrix of the p_i , namely $[Var(p_r, p_s)]$. Substitution of sample estimates for the elements of (11) then yields an estimate of the variance of \hat{I} . In this report, we have assumed simple random sampling so that we have taken the estimate of the variance-covariance matrix to be given by

$$var(p_i) = p_i(1-p_i)/n$$

$$cov(p_i, p_j) = -p_i p_j/n$$

and we have estimated the vector d by substituting the sample estimates p_i in the analytic expressions for the derivatives.

Summary of Results

There are several points of interest on which we should focus our attention in summarizing the results of this study. First, are the indexes of inconsistency for identical items from the two samples the same? To the extent to which they differ, is the difference due to the two census-taking procedures having different expected values or is it due to one of the procedures causing larger simple response variances? Second, are the indexes of inconsistency for identical items from either or both of the two samples comparable to the indexes derived from other studies? For which items does the data-gathering procedure make a difference? Which kind of data-gathering procedure makes the largest difference? Third, what is the size of the intraclass correlation among units in the assignment of the same interviewer? This correlation, even though small, can substantially increase the size of the total variance of census statistics. Let us consider each of these points in the paragraphs that follow.

Comparison of indexes of inconsistency derived from different data-gathering procedures

We can compare the weighted average \hat{I} of the indexes of inconsistency for the same classification systems for the two samples. Caution must be observed in comparing

the average \hat{I} for different classification systems, since these indexes are functions of the number of categories in the classification as well as the distribution of the population over the categories. Thus, it is tempting to say that since the average \hat{I} for vacancy status in Sample I is about .14 and for year built is .28 that the vacancy status question is subject to less response variability than the question on year built. But, the number of categories differs and the distribution of the population is different, so that such a comparison is only an indication that there might be less variability in the responses to one question than the other. One should then examine the tables which show the cross-classification of the data with great care.

However, in comparing the averages for the same classifications for the two samples, we find that of the 11 housing classifications studied, average \hat{I} from Sample I was larger than that from Sample II for eight of the classifications. Of the 33 population classifications, average \hat{I} from Sample I was larger than that of Sample II for 27 of the classifications. This is one indication that the use of the gross difference rates to estimate the simple response variance will give us different results from Samples I and II, with Sample I giving us larger estimates.

If, instead of comparing the averages, we compare the indexes of inconsistency category-by-category, we find the following:

Of 36 housing items, the index for Sample I was larger than that of Sample II for 24 of them. (There were 38 items for which comparisons could not be made because the sample size was too small or because the proportion of the population in the specified class was less than .01.)

Of 263 population items, the index for Sample I was larger than that of Sample II for 191 of them. (There were 86 items for which comparisons were not made because the sample size was too small or because the proportion of the population in the specified class was less than .01.)

Thus, on a rather crude basis, we have some reason to believe that the data-gathering procedure used in Sample I is producing different results from that used in Sample II.

Is the difference due to a difference in expected values of the census process and an enumerative process, or is it due to a difference in simple response variances? For only five of the housing items was B'^2 large enough to affect the third decimal place and the change was never larger than .003. For only 19 of the population items did B'^2 affect the third decimal place. The largest value of B'^2 was .008, occurring only once. Therefore, we shall assume that for most of the items, there was a difference in the simple response variances with Sample I producing a somewhat larger simple response variance. Of course, the difference may also have been caused by a difference in the values of γ^2 for the two samples. A more detailed analysis is in the next section.

To what extent are the estimates of simple response variance from Samples I and II different from those produced in other studies? These comparisons are available only for characteristics of the population. Comparisons were made with data from three different studies. The first of these is the CPS-Census Match, which is described

in ER60, No. 5 [8] of this series. In this study, data were matched from the Current Population Survey (CPS) and the census for identical households. No reconciliation of differences was attempted. The CPS interview was conducted within a month of the census interview, in some cases prior to the census interview. For many of the population items compared, the indexes of inconsistency were much larger as estimated from the CPS-Census Match study than from the data of Samples I and II. This may reflect the considerable difference in the general conditions of the CPS and the census. However, for occupation, industry, and weeks worked in 1959, the measures were generally of the same magnitude.

A second study which afforded the opportunity of making comparisons was the Employer Record Check (ERC), described in ER60, No. 6 [9] of this series. Comparisons could be made only for occupation and industry items. In the ERC, there was no second interview with the respondents. Instead, employers were asked to report by mail on the job descriptions and job titles of a sample of persons who had been enumerated in the census. A list of the industries in which these sample persons worked was sent to the Social Security Administration who supplied industry classification codes. (The list of sample persons was not sent to the Social Security Administration, only the industries.) The indexes of inconsistency were roughly comparable with those from Sample II and somewhat smaller than those from Sample I. For the ERC, the value of γ^2 was zero and the simple response variance of the response to the second procedure was probably much smaller than the simple response variance of the response to the census interview.

A third source of comparison is the Content Evaluation Study (CES) described in ER60, No. 4 [7] and in ER60, No. 10 [12] of this series. In the CES, reinterviews were held 3 to 6 months after the census and most differences in response were reconciled. In this kind of procedure, we should expect a strong positive correlation between the two responses. Thus, the indexes of inconsistency are expected to be smaller for the CES as the result of the subtraction of the term which includes this positive correlation. Also, because of the reconciliation, we might expect the simple response variance of the reinterview response to be smaller than that of the census response. It was found that for fertility items, the indexes of inconsistency from the CES were not too different from those of Samples I and II (which were similar) unless the number of children was seven or more. For most of the latter cases, the CES indexes were smaller. For educational attainment, the CES estimates were usually smaller than the estimates from either Samples I or II. It was difficult to make any decision about the income items; for many, the CES estimates were smaller, but for others they were larger. About all we can say with assurance is that for many items, the CES estimates of response variance are underestimates because of the positive correlation between the original interview response and the reinterview response.

Probably the most interesting result is that the estimates of the indexes of inconsistency for the same characteristic were approximately the same regardless of the study or data-gathering procedure. For example, the average indexes of inconsistency for occupation items were .25, .20, .21, and .19, for Sample I, Sample II, the CPS-Census Match, and the Employer Record Check,

respectively. For categories for which there was a large index of inconsistency, it was large for every study. Thus, we can be somewhat reassured that even though the simple response variances for the different data-gathering procedures may be different, the differences are usually small.

Estimates of ρ , the intraclass correlation of response deviations in the same enumerator's assignment

From Response Variance Study I, we have estimates of $\rho \sigma^2$ for several characteristics, though not for all of those that we have estimates of σ^2 for in this report. If we divide the estimates of $\rho \sigma^2$ by the estimates of σ^2 , we have estimates of ρ .

The estimates of ρ for different characteristics are shown in the next chapter in the detailed results. The estimates are usually small, approximately .01. Occasionally, there were a few estimates somewhat larger.

These estimates were made using only the data from Sample II on the ground that estimates of σ^2 from this sample are more nearly unbiased. Also, estimates of $\rho \sigma^2$ from Response Variance Study I were those that reflected the enumerator effect, not those that gave the joint effect of enumerators and crew leaders.

Values of a coefficient of intraclass correlation of .01 are far from being unimportant. The total response variance of a statistic for an area covered by a single enumerator is expressed by

$$RV = \frac{\sigma^2}{n} [1 + (n-1)\rho]$$

where n is the number of units observed by a single enumerator. Thus, for example, if ρ is .01, and the area consists of 4,000 units of which 25 percent or 1,000 are included in the enumerator's assignment for the census sample data, this small correlation would increase the response variance by a factor of 10. For the case in which ρ is .05, the response variance is increased by a factor of 50. Thus, users of census statistics should become sensitive to the importance of these apparently small values of ρ .

Detailed Results

A. Housing items

Six different categories of housing statistics were investigated in this study. They were:

- Occupancy status, for all housing units
- Tenure, for occupied housing units
- Vacancy status (for sale, for rent, etc.) for vacant housing units
- Year built, by tenure, for all housing units
- Contract rent, for rented housing units
- Cost of utilities not included in rent, for rented housing units

Tables 1 through 11 show the data classified by the response to different housing questions in the census and reinterview for Sample I. The data have been weighted to reflect the probabilities of selection of the units so that they are estimates for the population included in areas

in which a two-stage census was conducted. The census classifications are shown in the boxheads and the reinterview classifications in the stubs. For example, in table 1, we see that 3,614,000 housing units were classified as vacant in the census. Of these, 47,000 did not report on occupancy status in the reinterview. Of the 3,567,000 units reporting, 48,000 were classified as occupied and 3,519,000 were classified as vacant in the reinterview. Tables 12 through 22 show comparable data for Sample II. In both sets of tables, the entries are rounded to thousands. Thus, the columns and rows may not add up to the totals shown.

Since these tables are based on sample data, the numbers are subject to sampling variability. Thus, estimates based on Sample I differ slightly from those based on Sample II.

For both Samples I and II, the total number of non-responses was usually larger in the reinterview than in the census. None of this was due to refusals, since refusals were not included in the study.

Comparison of indexes of inconsistency derived from different data-gathering procedures

Table A shows estimates of the indexes of inconsistency and estimates of their standard errors for selected housing characteristics for Samples I and II.

For both occupancy status and tenure, the estimates from Sample I are larger than those from Sample II. In Sample II for tenure, all of those units who reported "no cash rent" in the census reported identically in the reinterview. This was not the case in Sample I. Though it seems that the simple response variances from Sample I are larger than those for Sample II for the occupancy and tenure categories, we must be cautious in making any such statement in light of the sampling errors of the estimates.

For vacancy status items, we cannot make any direct comparisons by category since there were less than 100 vacant units in Sample II. Tables 3 and 14 giving the cross-classified data for Samples I and II, respectively, show considerably fewer off-diagonal cases for Sample II than Sample I. However, we would not expect much difference between the two samples for these items since for vacant units, the information could not be obtained by mail so that enumerators had to visit the units to get the data.

The averages of the indexes of inconsistency for items dealing with the year in which the structure was built are smaller for Sample II than for Sample I. This is an indication that the data-gathering procedure used in Sample I causes larger simple response variances than the data-gathering procedure used in Sample II. This is true for both owned units and rented units. On a category-by-category basis, many of the differences can be explained by sampling error, but the pattern leads us to believe that the two procedures are different.

Tables 4 and 15 for total units show fewer off-diagonal cases for Sample II than for Sample I; the same thing is evident for owner-occupied units in the cross-classified data shown in tables 5 and 16 and for renter-occupied

Table A. COMPARISON OF ESTIMATES OF INDEXES OF INCONSISTENCY AND THEIR STANDARD ERRORS FOR SELECTED HOUSING CHARACTERISTICS FOR TWO DATA-GATHERING TECHNIQUES

Category	Indexes of inconsistency ± standard error		Category	Indexes of inconsistency ± standard error	
	Sample I ¹	Sample II ¹		Sample I ¹	Sample II ¹

⁵ Does not meet publication standards because indexes of inconsistency are not shown for categories for which the proportion in the category was less than .01 of the total.

¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census procedure--mail questionnaires with followup of nonresponse.

²The standard error for this estimate was between .0010 and .0045.

³Not shown for characteristics for which less than 100 units were in the sample.

units in tables 6 and 17. Overall then, there seems to be more consistency in the responses of units included in Sample II.

Comparing the indexes of inconsistency on a category-by-category basis, we see that the indexes from Sample I are larger than those from Sample II, for 16 out of 18 items. The two exceptions were for the category "1959 or 1960" for owner-occupied units and total units.

Continuing the comparisons of the indexes of inconsistency by category, we see that of the 18 categories, most of the indexes for Sample II are within sampling error of those for Sample I. Since the sampling errors are large, it is difficult to say that any differences between the two sets of indexes are true differences. However, since the indexes are almost always larger for Sample I than for Sample II, it seems unlikely that these are estimates of the same parameter.

We turn now to items that apply only to renter-occupied units. These items are contract rent and costs for utilities for units for which utilities were not included in the rent. Many of the indexes are not shown here because the proportion of persons in the category was less than .01. (See page 5.)

For contract rent, the average index for Sample II is larger than that for Sample I. Further, for eight of the 10 categories, the indexes for Sample II are larger than those for Sample I. Thus, even though the sampling errors are large enough that we cannot say anything definitive about the relative sizes of simple response variances for Samples I and II for individual items, the pattern indicates that there are larger simple response variances for Sample II than Sample I.

For the four characteristics concerning costs of utilities, there are many categories for which indexes are not shown because the proportion in the category is less than .01. However, the average indexes were slightly larger for Sample II for cost of electricity and cost of fuel and slightly smaller for Sample II for cost of gas and cost of water. The indexes for these utility costs are fairly large, indicating a considerable lack of consistency in response.

We can conclude that statistics on contract rent are subject to relatively small simple response variances, but statistics on gross rent, including costs of utilities, are subject to large simple response variances. For these items, an effort should be made to make the questions easier to understand or the answers easier to record. Even with these aids, it is quite likely that the simple response variances will remain larger than those for contract rent since the gross rent items are more complex. People usually know their monthly rent without resorting to records but utility costs may vary by month and be more difficult to remember.

Estimates of ρ_r , the intraclass correlation of response deviations in the same enumerator's assignment

In Response Variance Study I, we estimated the correlated component of response variance for several housing items. In this study, we have six items which are identical to the items in Response Variance Study I. For those items, we have divided the estimates of $\rho_r \sigma^2$ from

Response Variance Study I by the estimates of σ^2 from Sample II. The results are as follows:

<u>Category</u>	<u>Estimates of ρ_r</u>
Year built, 1929 or earlier, all units	.016
Year built not reported	.0009
Occupied rented housing units, paying for electricity	.0026
Occupied rented housing units, paying for gas	.0050
Occupied rented housing units, paying for water	.0026
Occupied rented housing units, paying for fuel	.0007

The largest of these, about .02, is for year built 1929 or earlier. If the average number of units observed by a single enumerator is about 250 housing units, the correlated component has the effect of increasing the response variance by a factor of

$$(n-1)\rho_r = 250(.02) = 5$$

B. Marital status

In the census, all persons were classified into one of five marital status categories. These categories were: married, widowed, divorced, separated, or never married. It has been noticed in previous censuses and surveys that people who are divorced or separated are more likely to be reported incorrectly as married or single than persons who are in other categories. For example, a study was undertaken after the 1961 Israeli census [4] to investigate the discrepancy in the number of persons reported as divorced in the census compared with the Population Register. There was an undercount in the census. However, unless the reason for the undercount was a misinterpretation of the meaning of the categories, the person was probably reported in the same category in the reinterview. Thus, the difference is due to a bias, not to response variance. In this study, we see small indexes of inconsistency for all marital status categories, thus confirming the impression that differences are not due to the confusion of the meanings of the categories.

Tables 23 through 25 show the data classified by response to the question on marital status in the census and the reinterview for Sample I; tables 26 through 28 show comparable data for Sample II.

Comparison of indexes of inconsistency derived from different data-gathering procedures

Table B shows estimates of the indexes of inconsistency and their standard errors for marital status items based on Samples I, II, and the CPS-Census Match. The averages of the indexes are also shown.

There is very little difference between Samples I and II for all persons 14 years old and over. This is evident from the average indexes and the indexes for the separate categories. However, even though the indexes for males are small, they are larger for Sample I than for Sample II, especially for the categories "divorced" and "separated." Tables 24 and 27, giving the cross-classified data

for marital status for males, show that there were far fewer males classified in the census as divorced in Sample I than in Sample II, but all of those in Sample II were classified identically in the reinterview. In fact, the large number of empty off-diagonal cells in table 27 shows there was very much less inconsistency in response for Sample II than Sample I.

Table B. COMPARISON OF ESTIMATES OF INDEXES OF INCONSISTENCY AND THEIR STANDARD ERRORS FOR MARITAL STATUS ITEMS FOR THREE DATA-GATHERING TECHNIQUES

Category	Indexes of inconsistency ± standard error		
	Sample I ¹	Sample II ¹	CPS-Census Match ²
Marital status, all persons 14 years old and over:			
Married.....	.01±.00	.01±.00	(4)
Widowed.....	.02±.00	.01±.01	(4)
Divorced.....	.02±.01	.02±.01	(4)
Separated.....	.04±.01	.04±.03	(4)
Never married.....	.01±.00	.01±.00	(4)
Average I.....	.01	.01	(4)
Males, 14 years old and over:			
Married.....	.01±.00	.01±.00	.02±.00
Widowed.....	.04±.01	.01±.01	.13±.02
Divorced.....	.07±.02	.00±.00	.37±.04
Separated.....	.05±.02	.00±.00	.52±.05
Never married.....	.01±.00	.01±.00	.03±.00
Average I.....	.01	.01	.05
Females, 14 years old and over:			
Married.....	.01±.00	.02±.01	.03±.00
Widowed.....	.02±.00	.02±.01	.07±.01
Divorced.....	.01±.00	.03±.02	.23±.02
Separated.....	.03±.01	.07±.04	.29±.03
Never married.....	.01±.00	.02±.01	.03±.00
Average I.....	.01	.02	.05

¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census taking procedure--mail questionnaires with followup of nonresponse.

²In the CPS-Census Match, an entirely different questionnaire was used in the other interview. The other interview was conducted by an experienced CPS interviewer. The CPS interviewer was paid and was trained in a different way from the census enumerator. It is therefore assumed that these figures are substantial overestimates of the index.

³The standard error for this estimate was between .0010 and .0045.

⁴Not shown for this study.

⁵Though the formal estimate of the standard error is shown as .00, the standard error is undoubtedly a small positive number.

The situation for females seems to be the reverse. The average index for Sample II is larger than that for Sample I. The indexes for the categories "divorced" and "separated" are somewhat larger for Sample II, though within sampling error of the estimates from Sample I.

Many of these differences might be explained if we knew who the respondent was in both the census and reinterview in both samples. A person in the household may be unaware of the marital status of the person for whom he is reporting. It may also be that in the Sample II procedure of a mail questionnaire, we are more likely to get the same respondent as in the census which tends to reduce the independence of the two responses.

We now compare the results from Samples I and II with those obtained in the CPS-Census Match. The average index of inconsistency is larger for the CPS-Census Match for every category. Except for the two categories "married" and "never married," the estimates from the CPS-Census Match are so much larger that it is hard to believe they are measuring the same parameter as in Samples I and II. A possible reason for this is that the different questionnaire used in the CPS introduces a substantial difference in procedure. The largest differences are for the divorced and separated categories. Since Samples I and II reflect data-gathering procedures very similar to the census data-gathering procedure, we assume that the estimates of indexes of inconsistency from those samples are more realistic than those from the CPS-Census Match.

C. Educational attainment

Tables 29 and 30 show the data classified by response to the question on educational attainment in the census and reinterview for Samples I and II, respectively. The data pertain to all persons 25 years old and over. One interesting item that shows up in table 30 points to a possible source of error. Of the 643,000 persons classified in the census as having the highest grade completed elementary 1 to 2 years, 162,000 were classified in the reinterview as having completed high school 2. This seems like a case of possible enumerator error in recording the information and filling in the circle on the wrong line of the schedule.

Table C shows estimates of the indexes of inconsistency and their standard errors for Samples I and II, and for the CES. Comparing first only Samples I and II, we see that the average index of inconsistency for Sample I is somewhat larger than that for Sample II. For 12 of the 15 categories, the index for Sample II is at least as small as that for Sample I, indicating there may be some tendency in the procedure in Sample I to cause larger simple response variances. However, in most cases the estimates for Samples I and II are within sampling error of each other.

Comparing the data from Samples I and II with the CES, the average index for the CES is almost identical with that for Sample II. For many of the categories, the indexes for the CES were about the same, but slightly smaller than the indexes for Sample II. Thus, the different data-gathering procedure used in the CES did not affect the level of simple response variance for educational attainment items. Indeed, if a substantial part of the error was caused by recording the answers incorrectly, a probing questionnaire with reconciliation of responses would not help in reducing the estimate of the index.

The levels of the index of inconsistency for the educational attainment characteristic indicate that this characteristic has a much more variable response pattern than the marital status characteristic. The indexes lie in the moderate range, with some of them extending into the high range. For example, the index for "elementary 1 to 2 years" was over .50 for all three studies. This is an indication that it might be useful to try a different wording of the question, a different set of instructions on how to complete the question, or a different way of recording the response.

Table C. COMPARISON OF ESTIMATES OF INDEXES OF INCONSISTENCY AND THEIR STANDARD ERRORS FOR EDUCATIONAL ATTAINMENT ITEMS FOR THREE DATA-GATHERING TECHNIQUES

Category	Indexes of inconsistency ± standard error		
	Sample I ¹	Sample II ¹	CES ²
Educational attainment, persons 25 years old and over:			
No school years completed.....	.34±.03	.25±.06	.24±.03
Elementary: 1-2 years..	.62±.05	.77±.12	.53±.06
3-4 years..	.43±.03	.41±.05	.37±.03
5-6 years..	.40±.02	.42±.04	.32±.02
7 years....	.56±.02	.45±.04	.38±.02
8 years....	.38±.01	.27±.02	.31±.01
High school: 1 year....	.57±.02	.39±.05	.40±.02
2 years....	.51±.02	.42±.04	.38±.02
3 years....	.54±.02	.51±.05	.46±.03
4 years....	.24±.01	.15±.02	.19±.01
College: 1 year.....	.45±.03	.52±.07	.35±.03
2 years....	.40±.03	.40±.06	.34±.03
3 years....	.58±.04	.39±.10	.38±.04
4 years....	.25±.02	.21±.04	.20±.02
5 years or more.....	.24±.02	.15±.04	.17±.02
Average I.....	.40	.32	.31

¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census-taking procedure--mail questionnaires with followup of nonresponse.

²In the Content Evaluation Study (CES), an entirely different, probing kind of questionnaire was used in the reinterview. The reinterview was conducted by experienced interviewers, paid and trained in different ways from census enumerators. Any difference in response between the census and reinterview was reconciled. This fact would be expected to result in underestimates of the index.

Estimates of ρ_R , the intraclass correlation of response deviations in the same enumerator's assignment

Estimates of ρ_R are available for five of the educational attainment categories. They are as follows:

Category	Estimates of ρ_R
Elementary, 1 to 2 years	.0026
Elementary, 8 years	.0048
High school, 4 years	.0084
College, 1 year	.0031
College, 5 years or more	.0006

The estimates of ρ_R are quite small. The effect on the total response variance could be as small as multiplying the simple response variance by .6 or as large as multiplying the simple response variance by eight, for the average number of people (about 1,000) observed by a single enumerator.

D. Number of children

Tables 31 and 32 show the data classified by response to the question on number of children in both the census and reinterview for Samples I and II, respectively. The data pertain to all women 14 years old and over who had been married at the time of the census.

Table D shows estimates of the indexes of inconsistency and their standard errors for Samples I and II, and for the CES. Comparing Samples I and II, there is close agreement between the average indexes for the two samples. Extending the comparison to the CES, we see the same level for the average index of inconsistency. The indexes by category also agree very closely. Thus, we see that for fertility items, simple response variances are estimated at about the same level regardless of the enumeration procedure.

Table D. COMPARISON OF ESTIMATES OF INDEXES OF INCONSISTENCY AND THEIR STANDARD ERRORS FOR NUMBER OF CHILDREN ITEMS FOR THREE DATA-GATHERING TECHNIQUES

Category	Indexes of inconsistency ± standard error		
	Sample I ¹	Sample II ¹	CES ²
Number of children, females, 14 years old and over, ever married:			
No children.....	.09±.01	.09±.02	.08±.01
1 child.....	.08±.01	.10±.02	.09±.01
2 children.....	.09±.01	.10±.02	.09±.01
3 children.....	.09±.01	.08±.02	.09±.01
4 children.....	.11±.01	.07±.03	.12±.02
5 children.....	.16±.02	.14±.05	.16±.03
6 children.....	.17±.03	.15±.06	.15±.03
7 children.....	.21±.04	.17±.07	.11±.03
8 children.....	.19±.05	.24±.11	(S)
9 children.....	(S)	(S)	(S)
10 children.....	(S)	(S)	(S)
11 children.....	(S)	(S)	(S)
12 or more children.....	(S)	(S)	(S)
Average I.....	.11	.10	.10

S Does not meet publication standards because indexes of inconsistency are not shown for categories for which the proportion of the population is less than .01.

¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census-taking procedure-- mail questionnaires with followup of nonresponse.

²In the Content Evaluation Study (CES), an entirely different, probing kind of questionnaire was used in the reinterview. The reinterview was conducted by experienced interviewers, paid and trained in different ways from census enumerators. Any differences in response between the census and reinterview was reconciled. This fact would be expected to result in underestimates of the index.

Another point which is obvious from looking at the indexes of inconsistency for number of children items is that almost all of the indexes are quite small. It would, therefore, not appear to be useful to try to reduce further the response variance for this characteristic.

Estimates of ρ_{r} , the intraclass correlation of response deviations in the same enumerator's assignment

Estimates of ρ_{r} are available for three items. These are shown below.

Category	Estimates of ρ_{r}
No children	.0054
1 to 3 children	.0033
5 or more children	.0030

As small as these estimates are, the total response variance is increased by a factor of at least three times the simple response variance in an enumerator's assignment of about 1,000 sample persons.

E. Labor force participation

In this section we look at two characteristics--whether people worked in 1959 or not, and the number of weeks worked in 1959 for those who worked. Tables 33 through

35 show data classified by response to the question on work status in 1959 in both the census and reinterview, for all persons 14 years old and over, for males, and for females for Sample I. Tables 39 through 41 show comparable data for Sample II. Tables 36 through 38 show data classified by response to the question on number of weeks worked in 1959 in both the census and reinterview for all persons 14 years old and over, for males, and for females, for Sample I. Tables 42 through 44 show comparable data for Sample II.

The question on the number of weeks worked in 1959 seems to have caused considerable confusion. Every cell of table 36, with the data for all persons 14 years old and over for Sample I, is filled. Every possible combination of reporting occurred, even to the point of persons reported as working 13 weeks or less in the census and 50 to 52 weeks in the reinterview. Table 42, presenting comparable data for Sample II, shows that not all combinations occurred for that sample. A similar pattern shows in the separate tables for males and females; in Sample I, all but one cell is filled. In Sample II, there are more empty cells.

Table E shows estimates of the indexes of inconsistency and their standard errors for Samples I, II, and the CPS-Census Match. For all of the characteristics except males working in 1959, the average indexes of inconsistency are somewhat smaller for Sample II than for Sample I. Thus,

Table E. COMPARISON OF ESTIMATES OF INDEXES OF INCONSISTENCY AND THEIR STANDARD ERRORS FOR LABOR FORCE PARTICIPATION ITEMS FOR THREE DATA-GATHERING TECHNIQUES

Category	Indexes of inconsistency ± standard error			Category	Indexes of inconsistency ± standard error

				Average ¹46	.41	.45

¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census-taking procedure--mail questionnaires with followup of nonresponse.

²In the CPS-Census Match, an entirely different questionnaire was used in the other interview. The other interview was conducted by an experienced CPS interviewer, sometimes by telephone. The CPS interviewer was paid and trained in a different way from the census enumerator. It is therefore assumed that the figures are overestimates of the index.

it seems that the data-gathering procedure used in Sample I produces slightly larger simple response variances than the procedure used in Sample II. Comparing the indexes category-by-category we see that the indexes for Samples I and II are quite close to each other for almost every category.

The indexes of Samples I and II agree with those from the CPS-Census Match. For some of the categories, some of the largest indexes for any set of characteristics are consistently large, no matter what reinterview procedure was used. For number of weeks worked in 1959, the category 48 to 49 weeks had an index over .80 for all three reinterview procedures. Tables 36 and 42 for Samples I and II show that most of those who were classified in the census as working 48 to 49 weeks were classified in the reinterview as working 50 to 52 weeks. Similarly, many of those classified in the census as working 50 to 52 weeks were classified in the reinterview as working 48 to 49 weeks.

Since the level of the index of inconsistency was fairly high for the item "number of weeks worked in 1959," it might be useful to try methods to reduce the variability in response. For example, one might experiment with the instruction that time spent on vacations or on illness or other such events should be subtracted from that total.

F. Occupation, industry, and class of worker

Tables 45 through 47 show the data classified by the response to the question on occupation in both the census and reinterview for all persons 14 years old and over, for males, and for females for Sample I. Tables 54 through 56 show comparable data for Sample II. Only major occupation classes are shown in the tables. The tables for females show considerably fewer off-diagonal cells filled than those for males, especially for Sample II. This may be because in the reinterview there often may have been a different respondent for males, but the same respondent for females. Or there may be a difference in simple response variances for males and females, with males having larger simple response variances. In Sample I, about 20 percent of all persons classified as laborers in the census were classified as operatives in the reinterview; in Sample II, the corresponding number was 10 percent. There was also considerable confusion between the categories of "managers, officials and proprietors" and "sales workers." In Sample I, about 8 percent who were classified as managers in the census were reported as sales workers in the reinterview; the corresponding figures for Sample II was 10 percent. There was also confusion between the categories of "craftsmen" and "operatives."

Tables 48 through 50 show the data classified by the response to the question on kind of business in both the census and reinterview for persons 14 years old and over, for males, and for females for Sample I; tables 57 through 59 show comparable data for Sample II. As was the case with the occupation characteristic, there were considerably fewer off-diagonal cases for females than for males, especially for Sample II.

Tables 51 through 53 show the data classified by response to the question on class of worker in both the census and reinterview for all persons 14 years old and over, for males, and for females for Sample I; tables 60 through 62 show comparable data for Sample II. For both Samples I and II, considerably more persons were reported in the Armed Forces in the reinterview than in the census; most were persons whose class of worker status was not reported in the census. For males, we see considerable confusion between the "private business" and "own business" categories.

Table F shows estimates of the indexes of inconsistency and their standard errors for occupation, industry and class of worker items for Samples I and II. Some estimates of indexes of inconsistency and their standard errors are shown for the CPS-Census Match and for the Employer Record Check (ERC).

Comparing the average indexes for Samples I and II only, the average indexes, for occupation, are smaller for Sample II than for Sample I for all persons, for males, and for females. For the industry characteristic, the average indexes are about the same for Samples I and II, indicating that the two procedures do not have different effects on the simple response variances for this characteristic. Similarly, for the class of worker characteristic, the average indexes for Sample II are only slightly smaller than those for Sample I.

On a category-by-category basis, of 30 possible comparisons for the occupation characteristic, the indexes for Sample I were larger than those for Sample II in 28 cases; for industry items, of 38 possible comparisons, the indexes for Sample I were larger than those for Sample II in 15 cases; for the class of worker characteristic, of 10 possible comparisons, the indexes for Sample I were larger than those for Sample II in seven cases. Thus, for occupation and class of worker, the pattern may lead us to believe that the data-gathering procedure of Sample I results in somewhat larger simple response variances. However, most of the differences between the two sets of indexes are small and could be explained by sampling error. Even though there might well be a difference in the simple response variances, the difference may be so small that it is unimportant.

Extending the comparisons to include the CPS-Census Match and the Employer Record Check, we see extremely consistent results with Samples I and II. For example, in the occupation items, there is an index between .30 and .36 for managers, officials, and proprietors and between .37 and .44 for laborers. When the index is high for one study, it is usually high for another. What is so surprising about this is really the consistent results from the Employer Record Check, since in this case a reinterview with the sample persons was not carried out, but a check was made with the employer instead. The results are encouraging since they seem to say that the differences such as those noted in data-gathering procedures do not affect the levels of the estimates of simple response variances.

Table F. COMPARISON OF ESTIMATES OF INDEXES OF INCONSISTENCY AND THEIR STANDARD ERRORS FOR OCCUPATION,
INDUSTRY AND CLASS OF WORKER CHARACTERISTICS FOR FOUR DATA-GATHERING TECHNIQUES

NA Data for this characteristic were not available from this study.

¹S Does not meet publication standards. Indexes of inconsistency are not shown for categories for which the proportion of the population in the category was less than .01. ¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census-taking procedure--mail questionnaires with followup of nonresponse.

²In the CPS-Census Match an entirely different questionnaire was used in the other interview. The other interview was conducted by an experienced CPS interviewer, sometimes by telephone. The CPS interviewer was paid and trained in a different way from the census enumerator. ³In the Employer Record Check, a questionnaire was sent to the employers of the sample persons, asking for job title. The Social Security Administration defined the kind of industry. Thus, there was no separate reinterview with the sample persons. ⁴Data for these categories were not tabulated for this study.

Estimates of ρ , the intraclass correlation of response deviations in the same enumerator's assignment

For six of the occupation items, data were available to compute estimates of ρ . These estimates are as follows:

Category	Estimates of ρ
Professional, technical workers	.0019
Farmers, farm managers, males	.0018
Clerical workers	.0034
Craftsmen, foremen	.0040
Operatives	.0038
Farm laborers, foremen male	.0012

The largest of these increased the total response variance by a factor of four and the smallest by a factor of 1.2 in a typical enumerator's assignment of 1,000 persons.

G. Veteran status

Table 63 shows the data classified by response to the question on veteran status in both the census and the reinterview for Sample I, and table 64 shows comparable data for Sample II. The data pertain to all males 14 years old and over. The "not reported" category is very large. Between 3.5 and 4.5 million men did not report their veteran status in the census; between 5 and 6-1/2 million did not report in the reinterview and about 1-1/2 million did not report in either. Of those who did not report in the census but did report in the reinterview, almost all had no service. The same was true of those who did not report in the reinterview but reported in the census.

In tables 63 and 64, the category "service not reported" refers to persons who were veterans but did not report the period of service.

Table G shows estimates of the indexes of inconsistency and their standard errors for the veteran status characteristic for Samples I and II. This characteristic was not investigated in any other study. The average indexes as well as the indexes for each category are smaller for Sample II than for Sample I. It is possible that the procedure used in Sample I causes larger simple response variances. Most of the differences are small and probably within sampling error. Altogether, the percentage of total variance due to simple response variance is small for most categories.

Estimates of ρ , the intraclass correlation of response deviations in the same enumerator's assignment

For one item, data were available to compute an estimate of ρ . This was for the category "World War II veterans." For this item, ρ was .021. This was one of the largest estimates. In an average assignment of 1,000 persons, the total response variance would be increased by a factor of 21 due to the correlated component of response variance. Thus, we see that even though the levels of simple response variance may

be low, the total response variances for these items could be quite large because of the enumerator effect.

Table G. COMPARISON OF ESTIMATES OF INDEXES OF INCONSISTENCY AND THEIR STANDARD ERRORS FOR VETERAN STATUS ITEMS FOR TWO DATA-GATHERING TECHNIQUES

Category	Indexes of inconsistency \pm standard error	
	Sample I ¹	Sample II ¹
Veteran status, males 14 years old and over:		
No service.....	.06 \pm .01	.04 \pm .01
Korean War.....	.14 \pm .02	.05 \pm .02
World War II.....	.06 \pm .01	.04 \pm .01
World War I.....	.08 \pm .02	.05 \pm .02
Other, including present.....	.35 \pm .03	.23 \pm .06
In service, but period not reported.....	(s)	(s)
Average I.....	.10	.06

S Does not meet publication standards. Indexes of inconsistency are not shown for categories for which the proportion of the population in the category was less than .01.

¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census-taking procedure—mail questionnaires with followup of nonresponse.

H. Wage and salary income

Tables 65 through 67 show data classified by response to the question on wage and salary income for both the census and reinterview for all persons 14 years old and over, for males, and for females for Sample I. Tables 68 through 70 show comparable data for Sample II. The "income not reported" categories are very large. Most of these people belong in the "no income" category and would have been placed there by the census edit program. Most of those not reporting on income were women who did not work and had no wage or salary income.

The number of persons who reported on wage and salary income is estimated to be about 60 million in each of the two samples. About one-fifth were persons who said in both the census and reinterview that they had no income. There was a good deal of inconsistent reporting. For example, of about 3-1/2 million persons who reported they made \$3,000 to \$3,499 in 1959 in the census interview, less than half in Sample I and just over half in Sample II said they had made that amount in the reinterview. The remainder of the persons were distributed over many other income categories.

Table H shows estimates of the indexes of inconsistency and their standard errors for wage and salary income items for Samples I and II and for the CPS-Census Match. For most of the items the indexes are between .3 and .5, indicating a moderate level of simple response variance. Comparing the average indexes for Samples I and II, there is a consistent pattern of smaller average indexes for Sample II. Looking at the indexes by category, we see that all but two of the Sample I indexes are larger than the corresponding index for Sample II. In many of the cases, the differences are too large to be explained by sampling error. It seems that for this characteristic, we are more likely to get smaller estimates

of the simple response variances by using the Sample II procedure.

When we compare the data from Samples I and II with the data from the CPS-Census Match, there is fairly close agreement between the indexes from the CPS-Census Match and those from Sample I. The average index for the CPS-Census Match lies between those for Samples I and II both for males and for females. The procedure used in the CPS-Census Match was closer to that of Sample I than that of Sample II. The question on wage and salary income on the CPS schedule is identical to that on the census schedule. Therefore, we might expect close agreement of those two studies.

Even though the indexes for the three procedures do not agree perfectly, the estimate from any one of them gives a good indication of the reliability of the item, with some exceptions. Thus, we may conclude the different data-gathering procedures affect the simple response variances to only a slight degree.

Estimates of ρ , the intraclass correlation of response deviations in the same enumerator's assignment

There are eight categories for which we can show estimates of ρ . These are as follows:

Category	Estimate of ρ
No income	.027
Males, less than \$3,000	.0024
Females, less than \$3,000	.0014
Males, \$3,000 to \$4,999	.0012
Females, \$3,000 to \$4,999	.0017
Males, \$5,000 to \$6,999	.0010
Females, \$5,000 to \$6,999	.0009
Males, \$7,000 to \$9,999	.0036

The estimate of ρ for the "no income" category was much larger than the other estimates. The enumerators may have assumed in many cases that housewives and

NA The data for this population were not available from this study.

S Does not meet publication standards. Indexes of inconsistency are not shown for categories for which the proportion of the population in the category was less than .01.

¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census-taking procedure--mail questionnaire with followup of nonresponse.

²In the CPS-Census Match an entirely different questionnaire was used in the other interview. The other interview was conducted by an experienced CPS interviewer, sometimes by telephone. The CPS interviewer was paid and trained in a different way from the census enumerator.

³Data for these categories were not tabulated for this study.

students had no income and filled in the blanks accordingly. On this item, the total response variance was increased by a factor of about 27 to reflect the correlated component due to the enumerator in a typical enumerator's assignment of 1,000 persons. The estimates of ρ_s are smaller for the other categories.

I. Self-employment income

Tables 71 through 73 show data classified by the response to the question on self-employment income in both the census and reinterview for all persons 14 years old and over, for males, and for females, for Sample I; tables 74 through 76 show comparable data for Sample II. Of the persons who reported on self-employment income, most had no income of this type. For Sample I, of those who said in the census that they had no income of this type, almost 97 percent agreed in the reinterview; the remaining 3 percent were distributed over every other cell of the table. Thus, there seem to be some major inconsistencies in reporting self-employment income. For example, in Sample I, of the 235,000 males who said in the census that they had self-employment income of \$3,500 to \$3,999, more of them said in the reinterview that they had no self-employment income than agreed on this amount.

Table I shows estimates of the indexes of inconsistency and their standard errors for self-employment income items for Samples I and II, for the CPS-Census Match, and the CES. Comparing the average indexes for Samples I and II, there is the usual pattern of smaller average indexes for Sample II. Because the proportion of the population in most categories was less than .01, we do not make any comparisons of indexes by category. For the limited number of comparisons available, the Sample II index is generally smaller than that for Sample I. This seems to indicate that, for self-employment income as well as wage and salary income, the data collection method used in Sample II produces somewhat smaller estimates of the simple response variances.

Data were tabulated on self-employment income in the CPS-Census Match and in the CES. However, the proportion of persons in most categories was less than .01, so we do not show many indexes of inconsistency. We can compare the average indexes for males and also for females. For females, the average index was about the same size as that for Sample I, for the CPS-Census Match, and for the CES. It was smaller for Sample II. For males, all four average indexes were about the same size.

Estimates of ρ_s , the intraclass correlation of response deviations in the same enumerator's assignment

Three items are available for the estimation of ρ_s . These are shown below:

Category	Estimate of ρ_s
Self-employment income \$2,500 or more	.0011
Males, less than \$3,000	.0011
Females, less than \$3,000	.0013

These are all small factors, and about the same size as those for the wage and salary income characteristic.

Correlations of this size could increase the total response variance by a factor of one in a typical assignment of 1,000 persons.

J. Other income

Other income refers to income from sources other than wage and salary or self-employment income, and includes income from pensions, social security payments, alimony, dividends, and other such income. Tables 77 to 79 show the data classified by response to the question on "other income" in both the census and the reinterview for Sample I for all persons 14 years old and over, for males and for females. Tables 80 to 82 show comparable data for Sample II.

As can be seen from tables 77 and 80, many people do not report small amounts of income. Thus, there are many entries on the line and column for "no income" on both the census and reinterview and in both studies.

Table J shows estimates of the indexes of inconsistency and their standard errors for "other income" items for Samples I and II, for the CPS-Census Match, and the CES. Comparing the average indexes of Samples I and II shows that they are lower for Sample II than for Sample I. They are also lower for all but one of the comparisons that can be made on a category-by-category basis. Unfortunately, there are few comparisons to be made since most of the categories contain less than one percent of the population. However, this limited comparison indicates that for the "other income" characteristic the procedure used in Sample II results in smaller estimates of the simple response variances.

For males and for females, we can compare data for a few categories with the CPS-Census Match and with the CES. For males, the average indexes for the four procedures are approximately the same; for females, the average index for Sample II is somewhat smaller than that for the other three procedures.

Estimates of ρ_s , the intraclass correlation of response deviations in the same enumerator's assignment

There are estimates of ρ_s available for two categories within this classification. These are shown below.

Category	Estimate of ρ_s
Other income, \$2,500 or more	.0046
Males, less than \$3,000	.0020

The estimates are of the same order of magnitude as those for wage and salary income and self-employment income. Correlations of this size could increase the total response variance by a factor of 2 to 4 in a typical assignment of 1,000 persons.

K. Total income

Total income includes all the money income for a person from wages and salary, from self-employment, and from other sources. Tables 83 through 85 show the data classified by the sum of the income reported for

NA The data for this population were not available from this study. S Does not meet publication standards. Indexes of inconsistency are not shown for categories for which the proportion of the population in the category was less than .01. ¹In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census-taking procedure--mail questionnaires with followup of nonresponse. ²In the CPS-Census Match an entirely different questionnaire was used in the other interview. The other interview was conducted by an experienced CPS interviewer, sometimes by telephone. The CPS interviewer was paid and trained in a different way from the census enumerator. ³In the Content Evaluation Study (CES), an entirely different, probing kind of questionnaire was used in the reinterview. The reinterview was conducted by experienced interviewers, paid and trained in different ways from census enumerators. Any difference in response between the census and reinterview was reconciled. This fact would be expected to result in underestimates of the index. ⁴Data for these categories were not tabulated for this study.

wages, in self-employment and in other income in the census and reinterview for Sample I. Tables 86 through 88 show comparable data for Sample II.

There was considerable inconsistency in the reporting of this item. This, of course, reflects the inconsistency of all the income items. Almost every cell of the table for total population is filled for Sample I.

Table K shows estimates of the indexes of inconsistency and their standard errors for total income items for Samples I and II, for the CPS-Census Match, and for the CES. Again, the average indexes are smaller for Sample II than for Sample I. This is to be expected since the pattern was the same for each of the three types of income combining to form total income. For 35 of the 44 categories for which comparisons can be made, the index for Sample I is larger than that for Sample II. Thus, the procedure used

in Sample II results in smaller estimates of the simple response variance. Of course, many of the differences could be explained by sampling error. As with each of the income items separately, we see that there may well be smaller simple response variances for the Sample II procedure, but the differences are usually not very large.

Comparing the indexes of Samples I and II with the CPS-Census Match and the CES, again there does not seem to be much difference in the estimates. If the effect of reconciling responses to the census and reinterview is to introduce a positive correlation between response deviations, then we would expect estimates of the indexes of inconsistency from the CES to be smaller than those based on Samples I and II. A counter-balancing effect may be the difference in the bias term. In any case, the indexes from the CES do not seem much different from Samples I and II.

Table K. COMPARISON OF ESTIMATES OF INDEXES OF INCONSISTENCY AND THEIR STANDARD ERRORS FOR TOTAL INCOME FOR FOUR DATA-GATHERING TECHNIQUES

¹S Does not meet publication standards. Indexes of inconsistency are not shown for categories for which the proportion of the population in the category was less than .01.

²In Sample I, the reinterview was conducted by a census interviewer. In Sample II, the reinterview was identical to the census-taking procedure--mail questionnaires with followup of nonresponse.

³In the CPS-Census Match an entirely different questionnaire was used in the other interview. The other interview was conducted by an experienced CPS interviewer, sometimes by telephone. The CPS interviewer was paid and trained in a different way from the census enumerator.

⁴In the Content Evaluation Study (CES), an entirely different, probing kind of questionnaire was used in the reinterview. The reinterview was conducted by experienced interviewers, paid and trained in different ways from census enumerators. Any differences in response between the census and reinterview were reconciled. This fact would be expected to result in underestimation of the index.

⁴The data for this population were not available from this study.

Table 1. ESTIMATES OF DIFFERENCES IN REPORTING OCCUPANCY STATUS OF ALL HOUSING UNITS, SAMPLE I
(Thousands of units)

Reinterview classification	Census classification							
	Total units	Occupancy status not reported	Occupancy status reported in census		Vacant in census			
			Occupancy status reported	Occupied	Vacant	Vacant year-round	Vacant-migratory worker	Vacant-seasonal

Note: In Sample II, a census questionnaire was sent to each household. The householder was asked to fill in the questionnaire and mail it to the census district office. Nonresponses and inconsistencies were followed up by census enumerators. The procedure was identical to the census procedure.

Table 69. ESTIMATES OF DIFFERENCES IN REPORTING WAGE AND SALARY INCOME OF MALES 14 YEARS OLD AND OVER, SAMPLE II

The procedure was identical to the census district office. Nonresponses and incomplete responses were followed up by census enumerators. The households were asked to fill in the questionnaire and mail it to the census district office.

- Represents zero.

Note: In Sample II, a census questionnaire was sent to each sample household. The householder was asked to fill in the questionnaire and mail it to the census district office. The procedure was identical to the census procedure. Nonresponses and inconsistencies were followed up by census enumerators.
